Clinical trial

A B S T R A C T

Background: The primary aim of our study was to evaluate the safety and potential toxicity of gemcitabine combined with microbubbles under sonication in inoperable pancreatic cancer patients. The secondary aim was to evaluate a novel image-guided microbubble-based therapy, based on commercially available technology, towards improving chemotherapeutic efficacy, preserving patient performance status, and prolonging survival.

Methods: Ten patients were enrolled and treated in this Phase I clinical trial. Gemcitabine was infused intravenously over 30 min. Subsequently, patients were treated using a commercial clinical ultrasound scanner for 31.5 min. SonoVue® was injected intravenously (0.5 ml followed by 5 ml saline every 3.5 min) during the ultrasound treatment with the aim of inducing sonoporation, thus enhancing therapeutic efficacy.

Results: The combined therapeutic regimen did not induce any additional toxicity or increased frequency of side effects when compared to gemcitabine chemotherapy alone (historical controls). Combination treated patients (n = 10) tolerated an increased number of gemcitabine cycles compared with historical controls (n = 63 patients; average of 8.3 ± 6.0 cycles, versus 13.8 ± 5.6 cycles, p = 0.008, unpaired t-test). In five patients, the maximum tumour diameter was decreased from the first to last treatment. The median survival in our patients (n = 10) was also increased from 8.9 months to 17.6 months (p = 0.011).

Conclusions: It is possible to combine ultrasound, microbubbles, and chemotherapy in a clinical setting using commercially available equipment with no additional toxicities. This combined treatment may improve the clinical efficacy of gemcitabine, prolong the quality of life, and extend survival in patients with pancreatic ductal adenocarcinoma.

1. Introduction

A diagnosis of pancreatic ductal adenocarcinoma (PDAC) carries one of the most dismal prognoses in all of medicine. Currently the 4th most

Gemcitabine has been the standard chemotherapeutic used in recent years and the most effective single agent. Compared to 5-fluorouracil, gemcitabine extends the survival by approximately one month whilst also improving clinical symptoms [6]. Recently, FOLFIRINOX (bolus and infusion of 5-fluorouracil, leucovorin, irinotecan, and oxaliplatin) emerged as a new chemotherapeutic option for patients with metastatic pancreatic cancer and an Eastern Cooperative Oncology Group (ECOG) performance status of 0–1. For this cohort of patients FOLFIRINOX is now the reference treatment. However, owing to the demonstrable toxicities and side effects of this therapy, gemcitabine is still the standard of care in patients with poor performance status or contraindication to FOLFIRINOX [7]. Furthermore, the combination of nanoparticle albumin-bound paclitaxel (nab-paclitaxel) and gemcitabine provides another new therapeutic option resulting with improved median survival of 1.8 months, compared to gemcitabine alone [8]. Despite these novel interventions, the reported increases in survival are minimal and we continue our wait for a therapy that will impact survival, provide a bridge to reductive surgery and ultimately cure PDAC.

Diagnostic ultrasound (US) imaging has been used in the clinic for > 50 years [9,10], with detection of pancreatic lesions dating back to the late 1960s [11]. Over the past 30 years, the use of ultrasound to detect PDAC has significantly increased [11–13]. Contrast-enhanced ultrasound uses stabilised gas microbubbles (MBs) to enhance the signal-to-noise ratio of the vasculature and allows clinicians to better visualise tissue perfusion. Twenty years ago, researchers discovered that upon application of ultrasound these microbubbles volumetrically oscillate. If these oscillating microbubbles were in the vicinity of cells, small pores could be formed increasing the uptake of macromolecules significantly [14–16]. Henceforth, the use of ultrasound and microbubbles to invoke biomechanical effects that increase the permeability of the vascular barrier and/or the extravasation of drug in a specific location is now commonly known as “sonoporation”.

Numerous researchers have shown in vitro and in vivo that sonoporation is a viable technique to improve drug delivery and improve therapeutic efficacy in various cell lines derived from pharyngeal [17], glioma [18], prostate [19,20], melanoma [21], and pancreatic cancer [22]. Sonoporation has also been used to open the blood brain barrier [23,24]. In general, sonoporation research is split into two camps: A) high-intensity, i.e., using inertial cavitation [9,25–27] and/or taking advantage of the thermal effects [28,29], and B) low-intensity, i.e., using stable cavitation [30,31] and non-thermal effects [32–34].

The use of high-intensity ultrasound without MB has previously been evaluated clinically and shown considerable success for pain therapy [35,36], ablation of breast fibroadenomas [37], opening the blood-brain barrier [38] and treatment of pancreatic adenocarcinoma [39]. Nevertheless, to our knowledge, there has been no clinical trial evaluating the efficacy of low-intensity ultrasound in combination with microbubbles to improve the chemotherapeutic efficacy in patients with PDAC.

We have previously demonstrated in vitro and preclinically in an orthotopic model of PDAC, enhanced treatment effects of gemcitabine with concurrent exposure to SonoVue® MB and US at low acoustic intensities [40]. Based on these preclinical results we initiated an open label phase I, single centre, safety evaluation study in PDAC patients by combining an ultrasound contrast agent and gemcitabine under sonication at clinical diagnostic conditions.

The primary objective of this study was to evaluate the safety and potential toxicity of gemcitabine combined with ultrasound contrast agent under ultrasound treatment in inoperable pancreatic cancer patients. The secondary objective was to evaluate a novel image-guided microbubble-based therapy, based on commercially available technology, towards improving chemotherapeutic efficacy, preserving patient performance status and prolonging survival.

2. Material and methods

2.1. Subjects

Over a 23-month period (January 2012–November 2013), we recruited ten consecutive voluntary patients with inoperable pancreatic cancer (KDR–10 C25.0–3) at Haukeland University Hospital. All had histologically verified, locally advanced (non-resectable Stage III) or metastatic (Stage IV) pancreatic adenocarcinoma. Needle biopsies were obtained either from the primary tumour or from a metastatic lesion. The tissue was processed in the diagnostic pathology laboratory according to standard routines (formalin-fixation, paraffin-embedment, staining with hematoxylin and eosin). The histology was evaluated by a senior pathologist with special competence in gastrointestinal pathology. Patients were ambulatory with an Eastern Cooperative Oncology Group (ECOG) performance status 0–1 (Table 1). Patients had to meet the standard criteria at our hospital for treatment with gemcitabine and no known intolerance to gemcitabine or SonoVue® (Bracco Imaging Scandinavia AB, Oslo, Norway) ultrasound contrast agent [45].

Historical data from PDAC patients undergoing equal gemcitabine treatment following the same inclusion and exclusion criteria, between 2009 and 2011 at Haukeland University Hospital, were used for comparison of treatment tolerance, safety, and overall survival. The only difference in treatment between the historical control group and our treated group was the addition of ultrasound and microbubbles following chemotherapeutic infusion. Gemcitabine was considered the standard of care for the treatment time period of the control patients and throughout this clinical study.

2.2. Chemotherapeutic and microbubble dosage

Two experienced oncologists, not participating in the study, were responsible for the chemotherapeutic treatment. The only divergence from normal administration practice was relocation to the research unit. We used the standard recommended treatment protocol of

| Table 1 |
| Clino-pathological characteristics of all pancreatic cancer patients. There was no statistically significant difference between the sonoporation treated cohort and historical control group in age, body mass index and blood chemistry. CA19-9 was not recorded in the historical control cohort. |

Comments:
Obligatory lab values for chemotherapy inclusion: B-Hemoglobin > 10, Neutrophils (polymorphonuclear leukocytes) > 3.5, Platelets > 150, Bilirubin > 75.

* One sonoporation treated patient exhibited abnormally high CA19-9 values at 4608 U/mL hence not included in average CA19-9 values.
gencitabine hydrochloride (Gemzar®, Eli Lilly & Co., Indianapolis, USA) [45]. Specifically, an initial phase of intravenous gencitabine infusion was administered at a frequency of one cycle per week for seven weeks followed by a one-week pause. Subsequent cycles of infusions were given once weekly for 3 consecutive weeks out of every 4 weeks. Treatment pauses or any dose adjustments were administered according to standard guidelines [43, 45]. Chemotherapy was continued as long as the treatment was beneficial [46]. The patients were monitored according to the requirements for Phase I studies [47].

Maximum plasma concentration of gencitabine is achieved after 30 min at which point sonoporation with Sonovue® was initiated to ensure maximal possible tumour exposure [48]. Clinically approved Sonovue® ultrasound contrast agent was used as the microbubble for sonoporation [49]. Ethical approval limited treatment to the use of a single vial of microbubbles, parallelising traditional imaging protocols. Due to the acoustic emission limitations of the clinical diagnostic scanner (cf., Section 2.4) we chose to maximise the treatment time to achieve the longest active sonoporation time (i.e., time when ultrasound waves and microbubbles were present). The expected in-vivo life of microbubbles was 4–5 min, hence we chose to inject boluses every 3.5 min to ensure microbubbles were present continuously throughout the whole treatment. Previous experience [50] showed that we were able to detect microbubble using non-linear ultrasound imaging using 0.5 ml boluses [51]. Due to these requirements, microbubble dosage results in 0.5 ml of Sonovue® followed by 5-ml saline every 3.5 min, immediately after the end of the intravenous infusion of gencitabine [43]. A complete vial was used in 31.5 min. The total dose of contrast agent used throughout each treatment was within standard clinical practice [52].

2.3. Ultrasound scanner configuration

In our previous studies we determined that sonoporation had a significant therapeutic effect when using long pulse durations, specifically 40 μs pulses every 100 μs (i.e., a duty cycle of 40%) [41, 44]. This resulted in minimal acoustic energy deposition within FDA and IEC guidelines and maximum therapeutic efficacy [53, 54]. In this clinical study, an unmodified clinical diagnostic ultrasound scanner (LOGIQ 9, GE Healthcare, Waukesha, WI) in combination with a 4C curvilinear probe (GE Healthcare) was used to apply the therapeutic ultrasound. Unfortunately, it is not possible to generate such long duty cycles with an unmodified clinical diagnostic machine, due to technical limitations. In addition, such long duty cycles would severely degrade the image resolution. Hence, we attempted to maximise the ultrasonic duty cycle emitted by the clinical machine, whilst keeping linear waves, to avoid bubble destruction and energy deposition at higher harmonics.

In order to determine the ideal settings, the machine was characterised and calibrated in a bespoke, automated, 3-axis ultrasound characterisation chamber filled with filtered, degassed, deionised water. To waterproof the probe prior to submersion, the transmission surface was covered in AQUASONIC® ultrasound transmission gel (Parker Laboratories, Fairfield, NJ), and subsequently covered using a latex ultrasound probe cover (Sheathing Technologies, Inc., Morgan Hill, CA). The probe was locked in place and a range of acoustic emission conditions were evaluated with the aim of reaching the longest duty cycle possible for the longest period possible. These acoustic emission conditions were considered optimal in relation to the limitations of the clinical ultrasound system emission configuration conditions. The device optimized acoustic conditions resulted in a derated MI of 0.2 (0.27 MPa peak-negative pressure), a 0.3% duty cycle with a center emission frequency of 1.9 MHz, and a spatial-peak temporal-average intensity of 0.25 mW/(cm) [2]. Specifically, the beamformed ultrasound bursts consisted of 4 cycles (2.1 μs) every 21 ms, i.e., a transmission duty cycle of 1%. Following the completion of the 12 ultrasound packet transmissions, there was a transmission pause allowing for echo capture and image reconstruction resulting in an overall duty cycle of 0.3%. The center frequency of 1.9 MHz was ideal as it was close to the natural resonance of the Sonovue® microbubbles [55]. At an MI of 0.2, only stable cavitation was expected to be induced throughout treatment. These acoustic emission conditions resulted in a 1-cm thick treatment slice based on a –3 dB contour [43].

To make sure that treatment only occurred at the target, i.e., the tumour, the image plane and non-linear contrast region of interest (ROI) was limited to the tumour area + 1 cm surrounding area. We avoided treating any liver or bowel area. The acoustic focal depth was placed at the centre of the tumour. The expected treatment height, based on a –3 dB contour was 3 cm above and below the acoustic focus depth.

This image-guided therapy model is based on the expectation that treatment only occurs where the ultrasound and microbubbles are present, i.e., what is being imaged.

The ultrasound probe was re-calibrated every six months to ensure acoustic consistency. The exact acoustic conditions and the ultrasound field map are thoroughly described in our previous publication [43].

2.4. Transabdominal ultrasound

Routine abdominal US imaging [56] was performed during the last 10 min (T = 20 min) of chemotherapeutic delivery using the same LOGIQ 9 clinical diagnostic ultrasound scanner as for treatment. The ultrasound probe was attached to a ball–head mount allowing for initial free-hand scanning. Once in the optimal position for treating the tumour, with the largest diameter targeted, the ball–head mount was locked and the ultrasound probe was kept in this position till completion of the treatment [43] (cf., Fig. 1). The optimal treatment position of the 4C clinical diagnostic ultrasound probe to ensure a clear acoustic path to the tumour without any obstructions such as stomach and bowel air varied per patient. This was achieved by following established diagnostic protocols for imaging the pancreas [56, 57]. In general, the probe was positioned in the epigastric region with the acoustic propagation path pointing towards the pancreatic tumour. The azimuth and elevation of the probe was adjusted to avoid any air pockets and liver tissue. The patients were allowed to lie in their most comfortable position prior to locating the tumour and locking the transducer in place. The patients were consulted if any discomfort was felt, and pressure adjustments were made if necessary. The large vasculature near the primary tumour was visualized using non-linear contrast mode in order to validate that microbubbles were being sonicated near the target tumour. Patient breathing allowed for passive scanning of the tumour, as with each breath the tumour would move through the acoustic field. The amount of passive scanning varied per patient breathing volume. Breathing based passive scanning ranged between 1 and 3 cm at the tumour level.

The total duration of combined ultrasound and microbubble treatment was 31.5 min. Fig. 1 shows the experimental setup used to combine chemotherapy, ultrasound, and microbubbles. Panel A shows the time course of each treatment cycle whilst Panel B shows a photograph of the ultrasound positioned to treat the tumour.
2.5. Pharmacokinetic evaluations

Analytical methods for pharmacokinetic (PK) evaluations were developed in parallel to the clinical study [58]. Whole blood samples were collected sequentially into prechilled heparinized tubes at the following time-points: \( T = 0, 30, 60, 120, 180 \) and \( 240 \) min. Tubes were spiked with the cytidine deaminase inhibitor tetrahydrouridine to prevent deamination of gemcitabine to dFdU [58]. Plasma and mononuclear cells were separated from whole blood as described previously. Concentrations of gemcitabine and dFdU were measured in plasma using in-house LC-MS/MS methods [58].

2.6. Monitoring

All patients underwent dual-phase computed tomography (CT) imaging \( \pm 3 \) weeks before study inclusion. Routine abdominal CT was performed every 8th week where maximum tumour diameter was quantified by independent radiologists. Tumour size and development was characterised according to the Response Evaluation Criteria in Solid Tumours (RECIST). Positron emission tomography (PET) imaging with F-18-fluoro-deoxyglucose (FDG) was performed prior to the treatment to determine if metastases were present.

Assessment of clinical state during the treatment also included an evaluation of the clinical benefit response and if surgical resection could be performed [46,59]. ECOG performance status was used as a proxy to monitor the effectiveness of the combined treatment. The ECOG scale describes patients’ level of functioning in terms of their ability to care for themselves, daily activity, and physical ability [46]. An ECOG grade of 0 indicates a patient who is fully active and able to carry on all pre-disease performance without restriction. An ECOG grade of 1 indicates that a patient is restricted in physical strenuous activity but ambulatory and able to carry out work of a light or sedentary nature, e.g., light house work, office work. An ECOG grade of 2 indicates a patient is ambulatory and capable of all self-care but unable to carry out any work activities. The patient is up and about > 50% of waking hours. An ECOG grade of 3 indicates a patient capable of limited self-care and confined to bed or chair \( > 50\% \) of waking hours. Hence, the longer a patient stayed below an ECOG grade of 3, the more effective the treatment was considered indicating an extended period of well-being. When a patient reaches an ECOG grade of 3, they are no-longer able to undergo gemcitabine chemotherapy.

Select patients also underwent diagnostic contrast-enhanced ultrasound following established clinical procedures [60]. Blood analysis was performed to evaluate if there was any acute toxicity.

2.7. Statistical analysis

The results are expressed as mean values \( \pm \) SD, unless otherwise indicated. Continuous data was analysed using t-tests, or Mann-Whitney tests if data were not normally distributed. Gehan-Breslow-Wilcoxon test and Log-rank (Mantel-Cox) test were used to compare survival. Variance is expressed through 95% confidence intervals. \( p < 0.05 \) was considered statistical significant. Patients removed from the study due to improvement were considered as intention to treat in the survival statistical analysis.
3. Results

3.1. Tumour targeting

The established guidelines for imaging the pancreas [56,57] allowed us to target the primary PDAC tumour, independent of tumour depth and size. Fig. 2 shows four representative ultrasound images of the PDAC tumours from our treated patient cohort captured prior to switching the diagnostic ultrasound scanner settings to “treatment mode”. In these images tumour depths ranges from 3.1 cm to 8.9 cm indicating that shallow or deep tumour did not inhibit tumour visualisation or targeting.

3.2. Toxicity evaluation

The direct parameters used to evaluate the toxicity of our treatment were clinical parameters including vital signs, ECG and blood chemistry. Overall, all data indicated that gemcitabine in combination with US did not induce any unexpected deviation or additional toxicities than chemotherapy alone.

One patient was hospitalised for a serious adverse event (SAE) unrelated to protocol therapy. Four SAEs occurred during protocol therapy. Two patients had symptoms indicating biliary obstruction and necessitated hospitalisation and rescheduling of the treatment. One was treated for pneumonia and one had fever due to cholangitis. The most frequent possibly treatment-related toxicities i.e., adverse events (AE) were abdominal pain (n = 9), nausea (n = 7), fever (n = 6), neutropenia (n = 6), and fatigue (n = 6) as described in Fig. 3. These events were registered as possibly related to protocol therapy. Since all the reported toxicities are expected side effects of gemcitabine, they were evaluated as gemcitabine related. All other AE were probably related to progression of underlying disease. There were no treatment-related deaths.

3.3. Blood biochemistry

No additional toxicity was observed. Blood values changed as expected. CA 19-9 and CA 125 levels decreased in 5 out of 8 patients measured, and 7 of the 10 patients, respectively.

When evaluating the levels of cancer marker CA 125 we observed a decline following combined treatment. A total of four out of ten patients went from elevated to normal counts and only a single patient went from normal to elevated counts. Whilst fewer measurements were made in the CA 19-9 counts a similar trend was also observed where three patients went from elevated counts to normal counts, five patients showed a decrease, two patients showed an increase, and only a single patient went from normal to elevated counts. No correlation between tumour size change and cancer marker count was observed (Supplemental Fig. 1).

Bilirubin, LD, ALAT and other liver parameters were in line with the expected variation under gemcitabine treatment. These were all considered to be normal blood biochemistry changes as expected from chemotherapy and disease course.

3.4. Clinical benefit and response assessment

The following methods were applied to evaluate the responses in the ten patients: RECIST, tumour size, ECOG grade and treatment cycles [59,61].

![Fig. 2. Representative ultrasound images showing the PDAC tumour in four of the ultrasound and microbubble treated patients. Tumour height and width are indicated by the yellow and green dotted lines. The ultrasound transducer was positioned to ensure no obstructions of the acoustical beam path to the tumour. This resulted in a unique ultrasound probe position per patient and treatment. Distance 1 and 2 indicate the tumour width and height respectively. Value D indicated the tumour centroid depth.](image-url)
The patients considered to be positive clinical responders were regularly evaluated by the Dept. of Oncology for FOLFIRINOX treatment or consolidative radiation therapy and surgery. After 12 treatment cycles, one patient was down-staged from 8.6 cm to 4.2 cm in tumour size and thereby became available for potentially curative therapy. She was removed from the clinical trial and underwent radiation therapy and subsequent pancreatectomy. Five patients exhibited partial responses as evidenced by reduction in tumour diameter. As a result, they were offered either consolidative radiation therapy or FOLFIRINOX treatment.

An average of 13.8 ± 5.6 and median 12.5 (range 5–26) treatment cycles of protocol therapy were delivered per patient. In comparison, our historical control group treated with the same chemotherapeutic protocol of gemcitabine alone received an average of 8.3 ± 6.0 and median 7 (range 1–28) treatment cycles (p = 0.008). Fig. 4A shows a whisker plot depicting the number and range of treatment cycles.

Table 2. Both Gehan-Breslow-Wilcoxon test and Log-rank (Mantel-Cox) test showed that the survival was significantly different with p = 0.0043 and p = 0.011, respectively.

3.5. Gemcitabine pharmacokinetics

Concentration profiles of gemcitabine and dFdU in plasma samples were in accordance with previous studies of gemcitabine-infusions of 800–1000 mg/m² administered to breast, lung, pancreatic and patients with various other solid tumours [48,62]. This demonstrates that the combination regimen did not seem to alter the systemic pharmacokinetics of gemcitabine. A representative concentration profile from one of the patients is shown in Supplemental Fig. 2.

4. Discussion

To our knowledge, this is the first human trial evaluating the use of low intensity ultrasound and microbubbles to treat cancer. All previous studies have only been performed in vitro or pre-clinically. Clinical studies using ultrasound for therapy have been focused on high-intensity ultrasound without microbubbles, or for pain treatment. Hence the effect of low intensity sonoporation therapy for PDAC in humans is unknown [44,63–65].

In our previous study [43], we presented the experimental protocol focusing on the technical aspects of implementing low-intensity sonoporation using a clinical diagnostic ultrasound scanner. We also presented pilot results of five patients briefly discussing the number of cycles and tumour sizes. In the current work we present the final results and clinical data of all 10 patients, including a comparison of overall survival. In addition, we provide a toxicity report regarding the safety of the study following 138 treatment cycles.

The primary aim of this Phase I study was to evaluate the safety and potential toxicity, when combing microbubbles, ultrasound, and a chemotherapeutic agent in patients with PDAC. Hence, in this clinical trial we only evaluated a total of ten patients, as required by the NMA. Overall, all data clearly indicated that this combination did not induce any additional toxicities.

4.1. Cancer markers

These results indicate that chemotherapy in combination with microbubbles and ultrasound may have a positive impact on tumour development. It is well known that there are correlations between CA 19-9 decline and both overall survival and time to treatment failure in patients treated with gemcitabine alone [66]. The limited number of patients in our Phase-I-trial does not allow us to make any further conclusions.
In our present work, we present all adverse events experienced by the patients independent of grade and severity (Fig. 3). This also includes adverse events due to the actual malignancy, or personal experiences. Other clinical studies typically only register adverse events that can be directly correlated to the treatment itself, with occurrences above 10% and grades ≥ 3 [45]. As adverse events are rarely registered clinically, we were unable to directly compare with our historical group. To aid comparison we have compared to values available in literature (c.f., Supplemental Fig. 3). In this Figure, we observe a 40% difference of abdominal pain. The primary symptoms of pancreatic cancer are abdominal pain and weight loss [67], as a result this symptom is rarely recorded. Nine out of our ten patients exhibited abdominal pain prior to treatment, hence we do not attribute this adverse event as treatment related. In contrast, in studies where weight loss was recorded, it was observed in nearly all patients. In our treated patient cohort, only 20% (2 patients) exhibited weight loss. Throughout this study all AE had already been previously associated with gemcitabine chemotherapy alone. This strongly suggests that there is no additional toxicity when combining ultrasound and microbubbles with gemcitabine chemotherapy.

4.3. Overall survival and well being

When the patients’ health deteriorates, and their ECOG status rises above 2, they are no longer able to undergo therapy. Hence, number of treatment cycles indirectly represents the physical well-being of the patient. Our clinical trial group was able to undergo 66% more cycles than our historical control group (8.9 months) and literature reports median survival of 16 months while gemcitabine + nab-Paclitaxel give a median survival of 12.2 months [69]. The observed median survival in our study far surpassed both these values using a less effective drug (Graphical Abstract). As sonoporation is not limited to any specific drug, inducing sonoporation with a more effective chemotherapeutic may further improve the therapeutic efficacy. In the case of combined chemotherapeutics, sonoporation could either be induced during or after infusion of all drugs, or at a time point where all chemotherapeutics are in the bloodstream.

4.4. Other chemotherapeutic options

Whilst gemcitabine is no longer considered at the forefront of chemotherapeutic treatment for PDAC, it was the first choice treatment when this clinical trial was initiated [68]. Other drugs and drug-combinations such as FOLFIRINOX and Gemcitabine + nab-Paclitaxel are now considered state-of-the-art [7,8]. As this trial was initiated using Gemcitabine we could not modify the protocol when other drugs and drug combinations reached the forefront of PDAC chemotherapeutic treatment. Gemcitabine is still commonly used worldwide for the treatment of PDAC, hence this protocol may allow for easier implementation.

When we compare median survivals of these patient groups from literature we see that FOLFIRINOX results in median survival of 11.7 months while gemcitabine + nab-Paclitaxel give a median survival of 12.2 months [69]. The observed median survival in our study far surpassed both these values using a less effective drug (Graphical Abstract). As sonoporation is not limited to any specific drug, inducing sonoporation with a more effective chemotherapeutic may further improve the therapeutic efficacy. In the case of combined chemotherapeutics, sonoporation could either be induced during or after infusion of all drugs, or at a time point where all chemotherapeutics are in the bloodstream.

4.5. Tumour perfusion

PDAC is well known to be a hypovascular tumour [70], meaning it has less perfusion than the tissue surrounding it. This is falsely correlated to no perfusion. Nevertheless, in the clinical field it is well known that PDAC still exhibits perfusion. An example of such hypovascular perfusion can be seen the Supplemental video 1 and Fig. 6. Fig. 6 shows a B-Mode image, contrast-enhanced image, and a perfusion curve of the aorta, healthy pancreatic tissue and the primary PDAC tumour. Microbubbles can be clearly distinguished in the primary PDAC tumour when comparing the primary PDMC tumour area in Fig. 6 A vs. B. The perfusion curve Fig. 6C, depicts non-linear contrast echo amplitude as
a function of time for three regions of interest (ROI). The results validate that microbubbles enter the PDAC tumour. At \( T = 0 \), i.e., the time of injection, no microbubbles are present (i.e., \(-68 \text{ dB}\) is the baseline). At around 25 s the aorta is the first ROI to reach maximum perfusion, as expected. The pancreas reaches maximum perfusion at around 27 s, whilst the PDAC tumour reaches maximum perfusion at around 32 s. The aorta shows the highest nonlinear echo amplitude, followed by the pancreatic tissue. The PDAC has the lowest nonlinear echo amplitude whilst still being 26 dB higher than the baseline, but only 5–10 dB lower than the pancreas. This indicates the tumour has lower perfusion than the surrounding tissue, yet is sufficiently perfused to allow microbubbles to enter.

It is important to note that our historical control group treated with gemcitabine alone has a median survival of 8.9 months, which is slightly higher than that previously reported in literature (6.7 months)\(^{[3,5,71]}\) indicating that our historical control group was not negatively biased.

4.6. Potential mechanisms of sonoporation in vivo

In vitro, sonoporation is typically evaluated on a cell monolayer allowing direct contact between the target cell line and microbubbles. In vivo, the microbubbles flow through the vasculature and capillaries allowing direct contact only with endothelial cells, resulting in enhanced uptake only by these cells or, in some cases, in deeper cell layers\(^{[72,73]}\). We believe that the therapeutic efficacy observed in this Phase I clinical trial cannot only be attributed to the potential increase of gemcitabine uptake in the endothelial cell walls. The interaction between the vascular barrier and microbubbles may result in increased fenestration size allowing deeper drug penetration\(^{[74]}\). It is also known that ultrasound in combination with microbubbles can increase intracellular stress signalling\(^{[75]}\). This increased stress, in combination with the chemotherapeutic may result in enhanced drug sensitivity. Nevertheless, further work needs to be performed, pre-clinically and clinically to ascertain the true mechanisms behind the improved therapeutic efficacy.

4.7. Limitations

Whilst all these results show great promise, we cannot make global assertions on the efficacy of ultrasound-enhanced chemotherapy based on this study. To further understand and validate these results it is paramount to perform mechanistic experimental studies and examine a larger patient cohort in a prospective randomized controlled Phase II trial.

The tumour size reduction was measured using the maximum tumour diameter. Whilst this method gives a representative overview of

**Fig. 6.** Contrast-enhanced ultrasound of the PDAC tumour in Patient 7. Panel A: B-mode image. Panel B: Contrast-Enhanced image using SonoVue® microbubbles. Pancreatic tissue, the PDAC tumour and aorta have been labeled. Microbubbles can be clearly distinguished in the PDAC tumour when comparing to the B-Mode image. Panel C: Perfusion curve depicting non-linear echo amplitude as a function of time for the three regions of interest: Aorta (yellow), pancreatic tissue (red) and PDAC tumour (cyan). The PDAC tumour exhibits a longer time-to-peak and lower perfusion than both the aorta and pancreas, yet is still adequately perfused for microbubbles to enter. Panels A and B are freeze frames of late phase perfusion, 57 s after microbubbles injection (c.f. white arrows in Panel C).
tumour progression it does not take into account the 3D structural change of the tumour. In our opinion, future work should address the treatment effect on the tumour volume and not only the maximal diameter.

The primary limitations of this study are that only a single 2D slice of the tumour was treated. Using a 3D ultrasound probe with further optimized acoustic conditions and modifying the microbubble type and concentration may improve the therapeutic efficacy [44]. The ultrasound emission conditions used here were severely limited by the clinical diagnostic scanner. In previous studies, longer duty cycles have shown to have a better therapeutic effect than short duty cycles [76]. Future work should aim to determine the ultrasound conditions that induce the highest therapeutic effect and to allow implementation of such conditions in the clinic.

There is currently no consensus on what is considered an ideal microbubble dose. At high dosages, the microbubbles may interact more with each other than the cells due to secondary Bjerknes forces [76]. Future work should evaluate and optimise the microbubble type and dosage.

In the field of sonoporation, it is typically assumed that the enhanced effect is due to the increase in local drug concentrations. In our work, we did not evaluate if the local drug concentration was increased and if this could be the reason for the enhanced effect. Future work should evaluate if there is an increase in local drug concentration, or if the improved therapeutic efficacy is due to increase or decrease in perfusion, or other intracellular responses.

5. Conclusion

In conclusion, our study indicated that chemotherapy in combination with ultrasound and microbubbles seems to be safe. No additional toxicity was observed when compared to chemotherapy alone. In our patient cohort, sonoporation has the additional benefit of improving the number of treatment cycles the patients were able to undergo and correspondingly extending the period of well-being. Significantly increased survival was also observed compared to a historical cohort of patients. Acknowledging the small treatment group with sub-optimal treatment conditions in this study, a larger study with improved acoustic conditions and microbubble delivery is essential to improve our understanding and validating our results. Nevertheless, in our opinion these novel results show great promise for ultrasound and microbubble enhanced therapy.
